Logistic Regression

The question is how should we model the relationship between

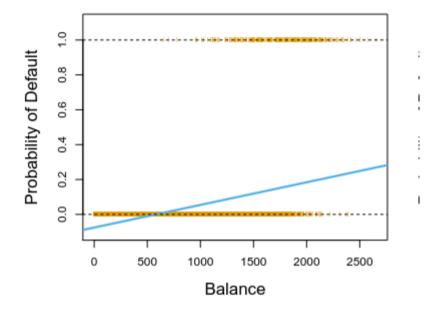

$$P(X) = \Pr(Y = 1|X)$$

- Relationship between the **Probability** of X and the **Classifying** Prediction for X
- Using 1 and 0 for the Response

Using Linear Regression model to represent these probabilities

$$p(X) = \beta_0 + \beta_1 X$$

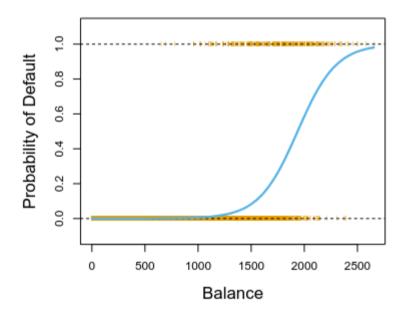

• If we fit the line to predict the **Probability**

Notice that the Balance Lower than 500 our prediction for the probability is negative

To avoid this problem we model p(X) to only fall between 1 and 0 for all values X Logistic Function which is a Sigmoid Function

$$p(X)=rac{e^{eta_0+eta_1X}}{1+e^{eta_0+eta_1X}}$$

• Any output of the **Logistic Function** Falls between 1 or 0

$$rac{p(X)}{1-p(X)} = rac{rac{e^{eta_0 + eta_1 X}}{1+e^{eta_0 + eta_1 X}}}{1-rac{e^{eta_0 + eta_1 X}}{1+e^{eta_0 + eta_1 X}}} = rac{e^{eta_0 + eta_1 X}}{1+e^{eta_0 + eta_1 X}} imes rac{1}{rac{e^{eta_0 + eta_1 X}}{1+e^{eta_0 + eta_1 X}}} = rac{e^{eta_0 + eta_1 X}}{1+e^{eta_0 + eta_1 X}} imes rac{1}{1+e^{eta_0 + eta_1 X}} = rac{e^{eta_0 + eta_1 X}}{1+e^{eta_0 + eta_1 X}} imes 1 + e^{eta_0 + eta_1 X}$$

$$ext{odds} = rac{p(X)}{1-p(X)} = e^{eta_0 + eta_1 X}$$

- the **quantity** p(X)/[1-p(X)] is called the odds can can only take values between 0 to ∞
- Values close to 0 indicates low probability
- Values close to ∞ indicate higher probability

- if p(X) = 0.5 the odds = 1 equal chance
- if p(X) = 0.8 the odds = 4 4x success chances

Probabilities vs Odds

- The odds are the **ratio** of something happening *divided by* something not happening
- The probability is the ratio of something happening divided by to everything could happen

$$Probability = \frac{Number \ of \ favorable \ outcomes}{Total \ number \ of \ possible \ outcomes}$$

$$\text{Odds} = \frac{\text{Probability of even occurs}}{\text{Probability event does not occur}} = \frac{p}{1-p}$$

Odds in logistic regression

Taking logarithm of both sides: log odds or logit

$$\log\left(rac{p(X)}{1-p(X)}
ight)=eta_0+eta_1 X$$

- the log of odds gives us a Linear equation which is easy to model and interpret
 Why we use the odds?
- **Probabilities** lives in the interval [0,1]
- Linear combinations like $\beta_0 + \beta_1 X$ lives on $(-\infty, +\infty)$
- The **odds** solves that by being in $(0, +\infty)$

In the **Linear Regression** β_1 gives the average change in Y associated with one unit increase in XIn the **Logistic Regression** β_1 does not correspond directly to the change in p(X), if β_1 is positive increasing one unit in X will increase the **Probability** p(X) but the increase depends on the current value of p(X)

$$eta_1 > 0 o ext{One unit increase X} o ext{Increase } p(X)$$

$$eta_1 < 0 o ext{One unit increase X} o ext{Decrease } p(X)$$

• The amount "Degree" of increase in the **Probability** p(X) depends on the current value of X

Estimating The Regression Coefficients

In **Linear Regression** we use the least squares to estimate the coefficients, in the logistic regression the **Maximum Likelihood**. **Intuition**:

- We seek estimates for \hat{eta}_0,\hat{eta}_1 such that we maximize the probability $\hat{p}(x_i)$
- More explanation in Maximum Likelihood Estimation

$$\mathcal{L}(eta_0,eta_1) = \prod_{i:y_{i=1}} p(x_i) \ \prod (1-p(x_{i'}))$$

- This called the Likelihood function
- Our estimates $\hat{\beta}_0, \hat{\beta}_1$ are chosen to **maximize** this likelihood function
- The least squares is a special case of maximum Likelihood

Same as **Linear Regression** we measure the accuracy of the estimated coefficients for the <u>Logistic Regression</u> by computing the **Standard Errors**, **Z-Test**, **Hypothesis Testing**

Once the **Coefficients** are estimated we can calculate the predicted probability for the observation X_i

Multiple Logistic Regression
